# 1 INTRODUCTION

Contrary to older processors, modern Intel CPUs implement a number of optimization techniques that increase their efficiency. One of which is the concept of out-of-order execution, which takes advantage of the mutual independence of instructions that would normally be executed sequentially. A second optimization technique is called speculative execution and involves the prediction of which branches are taken. With either technique, the CPU might encounter cases where the current CPU state must be rolled back to a previous one. For out-of-order execution, this happens if an instruction raises an exception (illegal memory access, for example). For speculative execution, this happens if a branch is mispredicted. A rollback causes some instructions that are currently being executed (in-flight) to continue execution for a short amount of time.

Even though rollbacks are meant to make sure in-flight instructions do not cause any lasting side effects on the microarchitectural state of the CPU, it was discovered that they can change the contents of caches and other buffers. The disclosure of both Spectre and Meltdown in early 2018 introduced a whole family of vulnerabilities that take advantage of both out-of-order and speculative execution to leak secrets over the processor's caches. And while the performance losses introduced by software and hardware mitigations are measurable, neither vulnerability can be exploited freely on a fully patched system. As a result, however, the process of trying to exploit one of the vulnerabilities for the sake of learning how they work in detail can be challenging. Apart from the software, which may be obtained by installing an older version of an operating system that does not implement any mitigations, one must also make sure their CPU is effected by the vulnerabilities and has not yet received any relevant microcode updates from Intel. Often times, this means that a user's personal computer does not meet these requirements.

We design and implement a graphical CPU emulator that supports single-step out-of-order and speculative execution and is vulnerable to select variants of Spectre and Meltdown. While it is a simplification in comparison to real hardware, the emulator allows its users to gain a better understanding of how exactly the two vulnerabilities work and can be exploited. Furthermore, the user may experiment with (ineffective) mitigations or implement their own microprograms that are executed once rollbacks are completed. We supply example programs that can be run by the emulator and serve both as an entry point for the user as well as the basis of our evaluation.

Firstly, chapter 2 briefly gives an overview of relevant components of vulnerable Intel CPUs, presents the concepts of out-of-order and speculative execution in greater detail, and introduces both Meltdown and Spectre to which the resulting emulator is supposed to be vulnerable. Secondly, chapter 3 further describes the target audience of the emulator and which variants of the vulnerabilities have been chosen, while chapter 4 documents the implementation of the emulator by describing each main component and explaining how rollbacks are implemented. Additionally, it contains an overview of the set of ISA instructions available to the user. Furthermore, chapter 5 explores the

graphical user interface by defining the goals its design is supposed to accomplish and documenting design choices and important features. Chapter 6 provides a demonstration of the emulator, which includes example programs, and determines how effective the implemented mitigations are. Finally, chapter 7 summarizes the other chapters, briefly reflects on how valuable the emulator might be to our target audience, and gives ideas for future improvements.

## 2 BACKGROUND

This chapter briefly covers the theoretical background needed to use the presented emulator and continue its development. The reader is assumed to have an understanding of elementary CPU concepts, such as pipelining and caching.

### 2.1 CPU

A CPU consists of a frontend, an execution engine, and a memory subsystem. As per Intel’s Skylake architecture [Wik], the frontend fetches the instructions, maintains a queue of instructions that are to be executed, and decodes them into simpler microinstructions, which are then communicated to the execution engine. Additionally, it is responsible for the branch prediction (see sec. 2.3). [Gru20]

The execution engine consists of multiple sets of execution units, each set being responsible for a specific type of microinstruction, such as loads, stores, or arithmetic. Further, the scheduler allows the execution units to work on independent instructions in parallel, while the reorder buffer makes sure that instructions retire in the correct order. A common data bus (CDB) connects the reorder buffer, scheduler, and execution units. Its purpose is further described in sec. 2.2. [Gru20]

Lastly, the memory subsystem handles all memory accesses of the execution units by maintaining caches and ensuring data is fetched from lower level caches or DRAM if needed [Gru20]. Most importantly, requests to data that is present in the caches is served faster than if it were not.

A visualization of the aforementioned components can be found in fig. 1.

### 2.2 OUT-OF-ORDER EXECUTION

As the name implies, out-of-order execution refers to the idea of executing instructions in a different order than the one in which they are given [Gru20]. With multiple execution units that run in parallel (as described in sec. 2.1), CPUs can take advantage of mutually independent instructions and execute them at the same time.

The basic realization of this concept is provided by Tomasulo’s algorithm [Tom67]. It introduces two components, the first of which is the reservation station, which collects the operands of instructions until they are ready to be executed by the execution units. Crucially, the corresponding execution units do not need to wait until all operands are present and can instead compute other instructions. The second component of Tomasulo’s algorithm is the Common Data Bus (CDB), which connects all reservation stations and execution units. Whenever a result is computed by an execution unit, the result is broadcast onto the CDB and thus made available to all reservation stations that are

**FIGURE 1:** Simplified overview an Intel Skylake CPU [Gru20, fig. 2.1]. For the memory subsystem, detailed knowledge of the load and store buffers, as well as the TLBs, is not required. The same applies to the allocation queue of the frontend.

waiting for it. This important step ensures that results are not written to registers first, just to be read again by other instructions that need them as operands.

Initially, according to Tomasulo, each set of execution units needed its own reservation station, however, more modern implementations by Intel use a single unified reservation station, called scheduler, that handles all types of instructions, rather than just one [Tom67] [Wik] [Gru20]. This can also be seen in fig. 1.

## 2.3 SPECULATIVE EXECUTION

Speculative execution allows a CPU to predict the outcome of comparisons and other branch instructions. This prevents stalls when waiting for the instruction that determines which branch is taken to finish. Similarly to out-of-order execution, rollbacks are needed in some cases. However, in addition to exceptions, they also occur if a branch was mispredicted. [Gru20]

To predict the outcome of branch instructions, CPUs include a branch prediction unit (BPU) [Gru20]. While available in different configurations, many modern CPUs record the most recent outcomes of a branch with a counter [Gru20] that is either incremented if the branch is taken, or decremented.

## 2.4 MELTDOWN AND SPECTRE

Meltdown [Lip+18] and Spectre [Koc+19] abuse out-of-order and speculative execution to leak data from memory addresses that are normally inaccessible to the attacker over the caches of the CPU.

### 2.4.1 MELTDOWN

On a high level, Meltdown [Lip+18] works by forcing exceptions when reading data inaccessible to the attacker and transiently encoding this data into the cache to retrieve it once the rollback has completed. What enables Meltdown is a small time window between an invalid memory access and the raising of an exception [Lip+18].

The Meltdown-US-L1 variant of Meltdown [Lip+18] to which the presented emulator is vulnerable works by accessing a memory address for which the attacker has no permission. Firstly, the attacker allocates an oracle array and ensures none of its entries are present in the cache. Upon loading the contents of the inaccessible memory location into a register, the attacker uses the value to access the array at a specific offset. When the rollback caused by the access violation has completed, the attacker measures the access time to each of the array entries to determine which one has been accessed. It is important that the data to be stolen is currently cached. While there are numerous other variants of Meltdown that differ from the basic variant mainly by how they force an exception and from which microarchitectural buffer they leak data, these types of attacks are out of scope.

### 2.4.2 SPECTRE

Spectre [Koc+19], on the other hand, relies on the CPU mispredicting a branch and transiently executing instructions that are not part of the correct execution path. This misprediction in a victim process can be induced by maliciously configuring the BPU (sec. 2.3). Depending on the instructions that are wrongfully executed by the victim, traces may later be found in the processor’s cache. Similarly to Meltdown, different variants of Spectre exist. The presented emulator is vulnerable to variant 1 of Spectre, which takes advantage of the CPU mispredicting the outcome of comparison instructions.

### 2.4.3 MITIGATIONS

The mitigations for Meltdown are available in both software and hardware, some of which are implemented in the emulator to allow users to experiment with them and determine their effectiveness. A first, rather simple, mitigation for Meltdown is to disable out-of-order execution [Lip+18], which would completely prevent an attacker from encoding the normally inaccessible data into the cache. Later revisions of Intel’s architectures introduced further mitigations. Although undocumented by Intel, researchers suspect the processor still performs the illegal read, but zeros out the data that is given to dependent instructions before raising an exception [Can+20]. The emulator implements this mitigation, which may be enabled by the user. Other mitigations deployed by operating systems, such as KTPI (or KAISER) [Lip+18], are highly effective, but out of scope, as there exists no operating system.

Unlike Meltdown, Spectre appears to be a design flaw. While one might argue that transiently computing on real values after it is already known an exception will occur is a bug, the behavior abused by Spectre is a direct consequence of speculative execution (sec. 2.3). As a result, an effective yet questionable mitigation is to simply disable speculative execution [Koc+19]. Alternatively, Intel recommends potential victim’s of Spectre v1 to use an “lfence” instruction where appropriate, which ensures prior load instructions retire before continuing, thus effectively disabling speculative execution for certain parts of an application [Int18]. A fence instruction is provided as part of the emulator’s instruction set.

An additional mitigation that works against both Meltdown and Spectre is to flush the entire cache after a rollback. While highly inefficient, it does prevent the retrieval of otherwise inaccessible data after the transient execution phase of the attacks. This mitigation can be realized using the emulator by a sequence of instructions (microprogram) that are executed after each rollback.

### 3 SPECIFICATION OF OUR TASK

todo

## 4 CPU EMULATOR/ BACKEND

In this chapter, we introduce the backend of our emulator program. It contains the elements of our program that emulate actual CPU components. Our emulator is based on information about modern real life CPUs, especially the x86 Intel Skylake architecture [Wik].

In our program, we model the distinct components of a real life CPU with a modular setup making use of the object oriented functionalities of Python3. Breaking up the source code into individual CPU components also makes it easier to understand and maintain. Additionally, we have made simplifications and modifications in comparison to a real life CPU, so the emulator is as clear and easy to understand as possible while still implementing an actual out of order execution and providing the necessary functionality for Meltdown and Spectre attacks.

In this chapter we firstly introduce the components of our CPU emulator, how they work (together) and which part of a real life CPU they emulate sec. 4.1. Then we explain how our emulator provides out of order execution and how it may differ from the general Tomasulo algorithm introduced in sec. 2.2. Subsequently, we show how we implemented rollbacks and exception handling, especially with regards to how our implementation allows for Meltdown and Spectre attacks sec. 4.3. Then we give an overview over our instruction set architecture sec. 4.4. Lastly we show how our emulator can be adapted for different demonstrations and attacks without changing the source code via a config file sec. 4.5.

### 4.1 CPU COMPONENTS AND OUR EQUIVALENTS/ MODELS (10-11 PAGES)

todo

#### 4.1.1 CPU

The primary purpose of the CPU module is to allow all other components to work together. That is, the CPU initializes all other components and provides interfaces to their functions, which allows the GUI to visualize the current state. In addition, the CPU provides functions which load user programs and a tick function that is called each cycle and does the following: instructions from the instruction queue are fetched from the frontend and forwarded to the execution engine, until either no more slots in the unified reservation station are available, or the instruction queue is empty. It then calls the tick function of the execution engine. In case of a rollback, the instruction queue maintained by the frontend is flushed. If the rollback was caused by a faulting load instruction, execution is resumed at the next instruction (as described in sec. 4.3). In case a branch was mispredicted, the frontend is notified and refills the instruction queue accordingly. If configured, corresponding

microprograms are sent to the instruction queue. Lastly, a snapshot of the current state of the CPU is taken.

The second purpose of the CPU is to provide the snapshot functionality which allows a user of the emulator to step back to previous cycles. The snapshot list is simply a list which grows at each cycle, where each entry is a deep copy of the CPU instance. However, this would imply that each snapshot maintains a full list of snapshots, where each entry contains a list of snapshots, and so on. To combat this, there is only a single global list of snapshots, and each snapshot entry maintains a reference and an index to its own entry. As a result, the default deep copy function is adjusted accordingly. Due to the low complexity of the programs we expect users to run, at the moment, no maximum number of available snapshots is configured.

#### 4.1.2 INSTRUCTIONS AND PARSER

todo

#### 4.1.3 DATA REPRESENTATION

todo

#### 4.1.4 CPU FRONTEND

In modern CPUs, the CPU frontend provides an interface between code and execution engine. It contains components to fetch and decode the instructions from a cache and supply them to the CPU in a queue. It is also involved in speculative execution by predicting the result of conditional jumps and supplying instructions to the execution engine accordingly. [Wik]

In our emulator we simplify the components and procedures. We also separate the branch prediction unit (BPU), that manages and predicts the results of conditional jumps, from the rest of the frontend. This makes our code easier to understand and makes potential future changes or additions to the BPU more convenient.

#### BRANCH PREDICTION UNIT (BPU)

The BPU of modern CPUs plays a vital role in enabling speculative execution. It stores information about previously executed conditional branch instructions and predicts the outcome of future branch instructions accordingly. The rest of the CPU can then speculatively execute further instructions at an address based on the predicted outcome of the branch instead of stalling until the branch instruction is processed by the execution engine. If the prediction was false, a rollback is performed on the speculatively executed instruction sec. 4.3. If the prediction was true, the execution is overall faster than without speculative execution.

Detailed information about the BPU of our modern base CPU is not widely available [Wik]. In general, the Gshare BPU of modern CPU consists of multiple components. It contains a branch target buffer (BTB) that holds the predicted target addresses for conditional branches. It also uses a

pattern history table (PTH), that can be implemented as a 2-bit-saturating counter, and a global history register (GHT) to predict whether a conditional jump will be taken or not. [SCA]

In our emulator, we forgo the BTB entirely. Real life CPUs benefit from stored target addresses since they have to expensively decode each branch instruction before they can work with the target address [Wik]. In our emulator, the parser decodes the jump labels from the assembler code and directly provides them to the frontend, so storing them in an additional buffer is unnecessary sec. 4.1.2. We further forgo the GHT because it is not strictly necessary to execute a Meltdown or Spectre attack. Additionally, our emulator and its behaviour are easier to understand and predict without it, which is important when implementing microarchitectural attacks for didactic purposes. The BPU of our emulator only consists of a PHT, which is enough for simple Spectre-PHT variants [reference-eval-spectre].

The default PHT used in our emulator holds an array called counter of configurable length to store several predictions. The instructions are assigned to different prediction slots by the last bits of their index in the instruction list. For each of the slots, the prediction can take the four different values from zero to three, where zero and one indicate that the branch will probably not be taken and two and three indicate that the branch is likely to be taken.

The source code for our emulator also contains a more simple BPU with only one slot for all instructions. Since the number of slots in the default BPU is freely configurable by the user, this simple BPU is now obsolete.

When the BPU is updated with an actual branch outcome from the execution engine, the prediction in the PHT is updated by a 2-bit counter. This means, that if the prediction was right, the counter remains at or updates to zero (strongly not taken) or three (strongly taken) respectively. If the prediction counter is at zero but the branch is actually taken, the counter is updated to one (weakly not taken). If it is at a one when the branch is taken, it is directly updated to three. The counter behaves similarly when it has the value two or three and the branch is not actually taken.

## INSTRUCTION QUEUE

In a real life CPU, the overall purpose of the frontend is to provide the execution unit with a steady stream of instructions so the backend is busy as much as possible and therefore efficient. In a modern x86 CPU, the frontend has to fetch x86 macro-instructions from a cache and decode, optimize and queue them repeatedly to provide the backend with a queue of  $\mu$ -instructions ready for issuing in the execution engine. [Wik]

In our emulator, except for the BPU, the functionality of the CPU frontend is bundled in frontend.py. It is significantly simplified compared to a real life x86 CPU, especially since we use only one type of instructions instead of distinguishing between macro- and  $\mu$ -instructions sec. 4.4. They are already provided as a list by the parser, which renders the decoding and optimization steps in the frontend unnecessary sec. 4.1.2.

The main task of our frontend is to act as interface between instruction list provided by the parser and the execution engine sec. 4.1.6. It provides and manages the instruction queue, which holds the instructions that the execution engine should issue next. Conditional branches with their respective

BPU predictions are taken into account when filling the queue. This enables speculative execution which is needed for Spectre attacks sec. 2.4.

The central component of our emulated frontend is the instruction queue. In our version, it does not only hold the instructions themselves, but also for every instruction in the queue, the respective index in the instruction list is stored. For branch instructions it also holds the respective branch prediction from the BPU at the time that the instruction was added to the queue. This additional information is needed by the execution engine to handle mispredictions and other exceptions sec. 4.1.6.

When adding instructions to the queue, the frontend selects them from the instruction list, adds the additional information for the execution engine and places them into the instruction queue until the queue's maximum capacity is reached. The frontend maintains a program counter (pc) that points to the next instruction in the list that should be added to the queue. When the frontend encounters a branch instruction and the branch is predicted to be taken, the frontend adjusts the pc to resume adding instructions at the branch target. If a branch was mispredicted, the frontend provides a special function to reset the pc and refill the instruction queue with the correct instructions.

Additionally, the frontend provides a function to add a  $\mu$ -program to the queue. It consists of a list of instructions separate from the parser instruction list. When adding the  $\mu$ -program to the queue, the frontend may exceed the maximum queue capacity. This functionality can be used to implement mitigations against microarchitectural attacks, e.g. by adding a  $\mu$ -program as part of the exception handling after an illegal load [**reference-eval-mitigations**].

The frontend provides interfaces to both read and take instructions from the queue. It also provides a function that combines taking an instruction from the queue and refilling it, . Additionally, the frontend has an interface for flushing the whole queue at once without taking the instructions from the queue. This can be used when demonstrating mitigations against microarchitectural attacks [**reference-eval-mitigations**].

The frontend provides further basic interfaces, e.g. for reading the size the instruction queue and reading and setting the pc. These are used by the other components during regular execution, e.g. when issuing instructions to the execution engine, but also to reset the queue to a certain point in the program after an exception has occurred sec. 4.3. Since our emulator only executes one program at a time, the other components can check via another interface whether the frontend has reached the end of the program.

89
90         mixture of both in one: only u-code, but more abstract than in real
91         life
92
93         do not need to think about page faults etc. anyways, do not need
94         overly complex instructions
95
96         reasoning behind the choice of instructions (manageable size and
97         instructions (e.g. no divide by zero) balanced with functionality
98         particularly wrt Meltdown)
99
100     ### config files (1 page)

```

```

94
95     what can be configured without changing the source code
96     why these variables? relevant for Meltdown?

```

## 8.6 OUR VISUALISATION AND USAGE/ FRONTEND (10 PAGES)

```

1  ggf. gemäß Anmerkung von Lenni umsortieren: die idee das UI nicht mit in
    die 'unsere designentscheidungen' zu nehmen, sondern im prinzip so als
    Manual abzukapseln finde ich eigentlich ganz gut. Müssen wir aber dann
    mal in der Praxis schauen. Soll ja keine didaktischen begründungen das
    manual zu sehr aufblähen, vllt wird das sinnvoll, dann einen teil des
    UI im "backend" kapitel einzubauen, und dann wirklich ein cleanes
    manual kapitel zu haben
2
3  ### general concept
4
5     goal: UI for the emulator with visualisation of CPU/ memory components
    and their contents
6
7     in terminal
8         maybe comparison to existing analysis tool/ debugger gdb
9
10    triggers/ controls the actual emulator
11        overview features, e.g. breakpoints, step-by-step and stepback
12
13    maybe which tools/ libraries were used?
14
15  ### features in more detail and their didactic purpose
16
17    breakpoints, step-by-step, stepback and more
18
19    challenges/ design choices during the implementation

```

## 8.7 DEMONSTRATION/ EVALUATION (7 PAGES)

```

1  what kind of system do we need/ did we use to run this?
2     which python Version?
3
4  ## general demonstration
5
6     brief example program showing all the features in a "normal" execution,
    e.g. adding stuff
7
8  ### Meltdown und Spectre demonstration
9
10     #### Example Program Meltdown

```

```

11
12     show example program
13
14     maybe compare to example program for real life architecture from
    SCA or literature (Gruss) if available
15
16     explain which Meltdown variant it implements
17
18     briefly highlight which components (we expect to) interact to make
    it work
19
20     how well does it work?
21
22     #### maybe example program spectre
23
24     same as Meltdown
25
26     #### mitigations
27
28     what is possible in our program as is
29         planned:    cache flush: microcode -> config file
30                   mfence in assembler (normally in compiler)
31                   aslr directly in program -> config
32                   flush IQ ->
33                   disable speculation und out of order (nice to have)
    -> config
34
35     how effective are these
36         in real life
37         in our program
38
39     what would be the necessary steps/ changes to the program for
    further mitigations
40         compare to changes in hardware by the manufacturers

```

## 8.8 CONCLUSION (1 PAGE)

```

1  recap goals
2
3  did we reach the goal of implementing a CPU emulator where a user can
    perform a Meltdown attack
4
5  how many Meltdown attacks are possible?
6
7  is Spectre possible?
8
9  mitigations
10     which mitigations did we implement

```

```
11     is this a good amount/ sample of real world mitigations or do we miss
12     important ones?
13
14     value to students:
15         how easy to use and convenient do we think our program is?
16         do we think this will be a good tool for teaching?
17         how accessible is it wrt different host architectures?
18
19     further work
20         more (detailed/ realistic) functionality for more Meltdown and Spectre
21         variants
22         more elaborate BPU with btb (and ghr) for more spectre variants
23         more mitigations
24         maybe nice to have wrt to the visualisation/ general UI functionality/
25         ISA?
```
